You are my PREVIS DIRECTOR inside Blender.

The attached HERO FRAME is the approved visual reference. Reconstruct it as a simple, editable 3D scene matching its composition, camera perspective, relative scale and major objects.

The hero frame already defines the final appearance. Your job is to create the clearest spatial simulation of the shot, not a beautiful 3D render.

We will use the Blender animation as a clay / white-model motion reference for Seedance 2.5, together with the original hero frame.

PRIORITIES

1. Camera 2. Composition 3. Blocking 4. Timing 5. Spatial relationships 6. Character/object trajectories

Visual detail is NOT a priority.

BUILDING RULES

Use simple geometry whenever possible. Use primitive shapes for architecture and props unless their real silhouette affects the composition.

Characters can be simple mannequins or low-detail proxies.

Use neutral matte clay materials. Avoid decorative textures, logos, text and unnecessary detail.
Everything must remain editable.
Keep logical objects separated and clearly named.

CAMERA
Treat the camera as the most important object in the scene. Match the approved hero frame as the starting composition before animating.
Define:
- starting camera position
- ending camera position
- camera height
- lens / field of view
- camera target
- path
- acceleration/deceleration
- framing at important beats
- foreground occlusion
- parallax

Do not use random camera movement.
ACTION
Break the performance into clear timed beats.

For each beat define:
- subject starting position
- subject ending position
- movement
- interaction
- screen direction
- camera relationship
Use simple animation cheats when they communicate the idea better than complex animation.

PHYSICAL REALISM PASS
Review the entire animation as if you were a senior cinematographer, camera operator, stunt animator and physics animator preparing this previs for live-action production.
The goal is NOT perfect mathematical motion.
The goal is motion that feels physically filmed in the real world.
Do not redesign the scene, composition or story. Preserve all approved beats, blocking and final framing.
Your job is to remove anything that feels like: CG animation, robotic keyframes, perfect spline motion, linear interpolation, floating objects, weightless movement, mechanical camera motion, unnatural acceleration, or instant starts and stops.

1. CAMERA — MAKE IT FEEL PHYSICALLY OPERATED
First identify what kind of real camera system could physically create this shot:
handheld operator

shoulder camera
Steadicam / gimbal
dolly
crane / techno-crane
slider
vehicle-mounted camera
drone
robotic arm
combination of physically plausible systems
Choose the closest real-world camera logic and rebuild the motion around its physical behavior.
The camera must have MASS and INERTIA.
Never allow the camera to instantly: start, stop, change direction, change height, or rotate.
Every major camera movement must contain believable:
anticipation → acceleration → travel → deceleration → settle.
Avoid generic Ease In / Ease Out.
Acceleration must respond to the distance being traveled, camera mass and intended energy of the shot.
Inspect the animation curves manually.
Remove: perfectly symmetrical curves, linear-looking transitions, constant-speed CG gliding, abrupt tangent changes, and unnecessary keyframes.
Favor continuous velocity and acceleration.

Avoid sudden changes in acceleration (“jerk”) unless motivated by an intentional physical impact.

2. REMOVE THE “3D CAMERA” FEEL
The camera should never feel like a floating point moving through coordinates.
It should feel attached to a physical device occupying real space.

Introduce extremely subtle organic imperfections appropriate to the chosen camera system.Do NOT add random camera shake.
Imperfections must have physical causality.
For handheld: use subtle human body drift, breathing, small delayed corrections and imperfect stabilization.
For Steadicam/gimbal: keep the shot smooth but allow tiny residual inertia, slight vertical drift and delayed rotational correction.
For dolly: movement should be highly stable, with strong horizontal consistency and extremely subtle start/stop inertia.
For crane: respect the arc and mechanical radius of the arm.
For drone: respect momentum, banking, acceleration limits and delayed directional correction.
Avoid perfectly locked XYZ motion unless the actual camera rig would produce it.
3. PAN / TILT / ROTATION
Camera rotation and camera translation must not feel like independent sliders.
They should influence each other naturally.
When following a moving subject, allow the camera framing to react with a slight human delay rather than mathematically tracking the subject perfectly.
Do not keep the subject unnaturally locked to exactly the same screen coordinate.
Allow tiny composition corrections.
For fast reframing: introduce a believable overshoot followed by a small correction when appropriate.
For slow cinematic movements: prioritize stability, controlled inertia and smooth acceleration.
Never use artificial constant rotation.
4. LENS AND PARALLAX
Review whether the virtual lens matches the perceived camera movement.
Avoid changing focal length merely to fake camera movement.
Prefer real camera translation whenever possible.
Check foreground, midground and background parallax.
The amount of parallax must agree with: camera distance, lens choice, camera velocity, and scene scale.
Make sure scale feels physically believable.
If the camera passes close to foreground objects, their screen-space velocity should increase naturally.
Do not allow objects to feel like flat layers sliding independently.
5. CHARACTER AND OBJECT PHYSICS
Review every animated subject for:
mass, gravity, momentum, friction, contact, balance,

inertia, drag, collision, and follow-through.
Nothing should begin or stop moving instantly unless physically justified.

For living characters:
Movement should originate from shifts in center of mass.
Before major movement, create believable preparation or weight transfer.
Feet must make convincing contact with the floor.
No foot sliding.
Pelvis and torso should respond to locomotion.
Head movement should not be perfectly synchronized with the torso.
Arms and secondary body parts should contain natural follow-through.
After large movements, allow subtle stabilization.
Avoid symmetrical robotic motion.
6. OBJECT WEIGHT
Every object must visually communicate its mass.
Heavy objects:
accelerate more deliberately, take longer to stop, have stronger momentum, and create more noticeable reaction during impacts.
Light objects: respond faster, are more affected by air resistance, and may oscillate or settle differently.
Do not animate all objects with the same easing profile.
Use different acceleration, damping and settling behavior according to material and mass.
7. GRAVITY AND FALLING MOTION
Any unsupported object must respect gravity.
Review falling arcs and vertical acceleration.
Do not use visually linear falling motion.
Thrown objects must follow believable ballistic trajectories unless another force is acting on them.
After impact: consider bounce, compression, sliding, rotation, friction, and settling.
Avoid exaggerated simulation unless the scene intentionally requires it.
8. COLLISIONS AND CONTACT
Inspect every moment where: feet touch floors, hands touch objects, characters sit, objects land, objects collide, doors move, vehicles interact with surfaces, or subjects cross close to environment geometry.
There must be no visible penetration, hovering or unexplained gap.
Contact should create an appropriate reaction.
When one object pushes another, motion must propagate through the interaction.
When a character touches something, their body should subtly react to the force.
9. SECONDARY MOTION
Add only secondary motion that strengthens realism.
Examples:
subtle body stabilization, hair lag, cloth follow-through, object vibration after impact, suspension movement, small camera settling, environmental reaction, delayed movement in loose components.
Secondary motion should FOLLOW the primary force.
It should never look like independent decorative animation.
10. TIMING
Review the scene at full playback speed.
Do not judge realism from isolated frames.
Identify any moment where the viewer would subconsciously feel:

“this moved too quickly” “this stopped too perfectly” “this feels weightless” “this feels animated” “the camera feels like a computer” “the character feels like a mannequin”
Fix those moments.
Realistic timing is more important than preserving exact keyframe timestamps.

You may adjust timings slightly while preserving the approved narrative beats.
11. DO NOT OVER-SMOOTH
Realism does NOT mean making every curve smooth.
Real movement contains: changes of intention, micro-corrections, impact, hesitation, momentum, and recovery.
Preserve motivated irregularity.
Remove mathematical perfection without introducing noise.
The final result should feel DIRECTED, not randomized.

12. FINAL CAMERA REALISM CHECK
Watch the animation once while ignoring the scene and looking only at the camera behavior.
Ask:
Could a real camera system physically perform this move?
Does the operator seem to anticipate the action?
Does the camera have inertia?
Does it accelerate and decelerate naturally?
Does framing breathe slightly instead of remaining mathematically perfect?
Does it feel like someone filmed this rather than a 3D viewport camera moving between keyframes?
If not, revise it.
13. FINAL ACTION REALISM CHECK
Watch again while ignoring the camera.
For every moving subject ask:
Where is its weight?
What force started this motion?
What force stops it?
Where is the center of mass?
What is touching the ground?
What should continue moving after the main action stops?
Does gravity affect it?
Does the timing match its apparent mass?
Fix anything without a convincing physical answer.
14. FINAL DELIVERY
After the realism pass:
Preserve the original approved shot design.
Clean unnecessary keyframes.
Refine animation curves.
Correct physically implausible acceleration.
Add restrained secondary motion.
Verify contacts and collisions.
Verify camera inertia.
Verify real-world camera feasibility.
Generate a new real-time viewport playblast.

Show me:
full playblast
camera velocity over time
the main camera animation curves
frames at 0%, 25%, 50%, 75% and 100%
Do not proceed to final generation until the motion no longer feels like a Blender animation.
TARGET:
It should feel like a real camera recorded a real physical event, and Blender merely reconstructed it.
